## ABSTRACT

Weighted automata generalize non-deterministic automata by adding a quantity expressing the weight (or probability) of the execution of each transition. In this work we propose an implementation of two algorithms for computing language equivalence in finite state weighted automata (WAs). The first, a linear partition refinement algorithm, calculates the largest linear weighted bisimulation for any given LWA (Linear Weighted Automata) through an iterative method, the second algorithm checks the language equivalence of two vectors (states) for a given weighted automata by using an additional data structure representing a congruence relationship between states. We then compare the two algorithms results on randomly generated automata samples, to verify their correctness and provide some runtime statistics.

## 1 Introduction

In [1], up-to techniques are defined for weighted systems over arbitrary semirings, while in [2], up-to techniques are defined for Linear Weighted Automata (LWAs), under a more abstract coalgebraic perspective. For ease of implementation, we focus only on weighted automata over the field of real numbers  $\mathbb{R}$ .

## 2 Preliminaries and Notation

**Definition 2.1.** A *weighted automaton* over a field  $\mathbb{K}$  and an alphabet  $A$  is a triple  $(X, o, t)$  such that  $X$  is a finite set of states,  $t = (t_a : X \rightarrow K)_{a \in A}$  is a set of transition functions indexed over the symbols of the alphabet and  $o : X \rightarrow \mathbb{K}$  is the output function. The transition functions  $t_a$  are represented as  $\mathbb{K}^{X \times X}$  matrices.  $o \in \mathbb{K}^{1 \times X}$  is represented as a row vector.  $t_a(v)$  denotes the vector obtained by multiplying the matrix  $t_a$  by the column vector  $v \in \mathbb{K}^{X \times 1}$ .  $o(v)$  denotes the scalar  $s \in \mathbb{K}$  obtained by multiplying the row vector  $o$  by the column vector  $v \in \mathbb{K}^{X \times 1}$ .  $A^*$  is the set of all words over  $A$ .  $\epsilon$  is the empty word and  $aw$  is the concatenation of a letter  $a$  to the word  $w \in A^*$ . A weighted language is a function  $\psi : A^* \rightarrow \mathbb{K}$ . A function mapping each state vector into its accepted language,  $\llbracket \cdot \rrbracket : \mathbb{K}^X \rightarrow K^{A^*}$  is defined as follows for every weighted automaton:

$$\forall v \in \mathbb{K}^X, a \in A, w \in A^* \quad \llbracket v \rrbracket(\epsilon) = o(v) \quad \llbracket v \rrbracket(aw) = \llbracket t_a(v) \rrbracket(w)$$

Two vectors  $v_1, v_2 \in \mathbb{K}^{X \times 1}$  are called language equivalent, denoted with  $v_1 \sim v_2 \iff \llbracket v_1 \rrbracket = \llbracket v_2 \rrbracket$ . One can extend the notion of language equivalence to states rather than for vectors by assigning to each state  $x \in X$  the corresponding

unit vector  $e_x \in \mathbb{K}^X$ . When given an initial state  $i$  for a weighted automaton, the language of the automaton can be defined as  $\llbracket i \rrbracket$ .

**Definition 2.2.** A binary relation  $R \subseteq X \times Y$  between two sets  $X, Y$  is a subset of the cartesian product of the sets. A relation is called *homogeneous* or an *endorelation* if it is a binary relation over  $X$  and itself:  $R \subseteq X \times X$ . In such case, it is simply called a binary relation over  $X$ . An *equivalence relation* is a binary relation that is reflexive, symmetric and transitive.

An equivalence relation which is compatible with all the operations of the algebraic structure on which it is defined on, is called a *congruence relation*. Compatibility with the algebraic structure operations means that algebraic operations applied on equivalent elements will still yield equivalent elements.

**Definition 2.3.** The congruence closure  $c(R)$  of a relation  $R$  is the smallest congruence relation  $R'$  such that  $R \subseteq R'$

**Definition 2.4.**

### 3 Algorithm

### 4 Implementation

The algorithms and data structures for this paper are implemented in the Go programming language. This implementation makes use of the *Gonum* library for numerical computations. We only import the Gonum libraries for matrices and linear algebra and visual plotting of samples and functions.

Real numbers are implemented with double precision floating point numbers, known as the `float64` type in the Go programming language.
